The Stratigraphical Range of Fossil Rhinoceroses in the Late Neogene of Europe and the Eastern Mediterranean

K. HEISSIG

Fossil rhinoceroses are common faunal elements in Europe and Western Asia during the late Neogene. They are a rather conservative group, not exhibiting many distinctive intrafamily characters, and rather complete skeletal material is needed to make an accurate specific determination. So the considerable later Neogene rhino radiation is largely masked by insufficient materials, making a step-by-step evolutionary reconstruction impossible. Often the most common and completely preserved materials belong to species having a vast chronologic and geographic distribution and providing little valuable information for correlation. However, other rhinoceros lineages are distinctive, and their migration and extinction events are often useful for correlation, albeit a rather coarse one. Only a single multispecific lineage can be tracked across the late Miocene–Pliocene boundary.

Despite the limitations seen for geochronologic correlations (de Bruijn et al. 1992), most rhinoceros species are good ecological indicators. The composition of rhino faunas varies even within the same temporal interval, and over short geographic distances. Unfortunately, rhino paleoecology is not yet well understood, leaving an unrealized treasure of information yet to be developed.

Time-Space Distribution of Middle Miocene–Pliocene European and West Asian Rhinoceroses

The Middle Miocene

During the middle Miocene the Aceratherini and Teleoceratini are the dominant rhinoceroses in both geographic areas considered here. *Brachypotherium brachypus*, *Aicornops simorrensis*, and *Hoploaceratherium*, with its successive species *H. tetracactylum* and *H. bavaricum*, occur throughout the entire region. In Europe the early Miocene holdovers, *Prosantorhinus germanicus*, a small

teleoceratine, and *Plesiaceratherium fahlbuschi*, an Aceratherini, become extinct in MN 6, contracting in their geographic distribution to Central Europe. The single occurrence of *P. mirallesii* in the isolated Central European locality of Georgensgmünd is also its last appearance. Of all these forms, only *Hoploaceratherium* was not already present in the late (MN 5) early Miocene. The successive species of *Hoploaceratherium* can be distinguished only by cranial characters.

The two Rhinocerotini species *Lartetotherium sansaniense* and “*Dicerorhinus*” *steinheimensis* first occurred in Europe during the late early Miocene, and there is no record of them in the Eastern Mediterranean. In the Eastern Mediterranean the influence of Asian faunas is seen by the occurrence of the elasmotherine genus *Begertherium* (Fortelius 1990) with its two successive species, co-occurring with the common genera *Aicornops*, *Hoploaceratherium*, and *Brachypotherium*. The genus *Diceros*, an African immigrant, is found very rarely in Eastern Mediterranean middle Miocene age horizons.

Unfortunately, the middle Miocene is represented by only a few French rhinoceros-bearing localities yielding the most common species. There is no record of rare Western European elasmotherine rhinos after MN 5. Rhinoceroses are not known during this time from Southern Europe, and only from two Southeast European localities, with the only determinable species being *Lartetotherium sansaniense*.

Some of these species have apparently been restricted to very peculiar habitats; their occurrence is not correlated with age or any particular sedimentary environment. Other species occurred over vast geographic areas and for long chronological durations. There is little known about the actual ecology of fossil browsing rhinos. All of the middle Miocene European forms would appear to have been browsers. Thenius (1951) and Heissig (1972) have remarked that *Brachypotherium* did not prefer swampy wood-

lands. The content of the shrub's wooden parts in the diet of the Aceratherini was probably higher than that preferred by *Lartetotherium sansaniense*. In contrast to the European woodlands, the Eastern Mediterranean semi-hypsodont Elasmotherini clearly inhabited dry areas and were adapted to abrasive food that had relatively poor nutritive quality. The presence of some European browsing species is indicative of the occurrence of restricted bush or woodland environments. The lack of Rhinocerotini corresponds with their preference for very soft plants.

The Late Miocene

Rhinoceros geographic distribution and ecological preferences change dramatically in the late Miocene, most probably because of regional climatic change. Sedimentary environments probably were also affected, because rhino-

bearing localities were now numerous in the Eastern Mediterranean, whereas Central European localities younger than the earliest late Miocene (MN 9) are rare.

The change is more radical in the Eastern Mediterranean than in Europe, and the dissimilarities in both regions increase considerably. Whereas no rhino lineage continues across the middle/late Miocene boundary in the Eastern Mediterranean region, the appearance of new elements in Central and Western Europe is followed by a gradual decline in the occurrence of survivors during MN 9 and MN 10. During this time we find the following surviving species: *Brachypotherium goldfussi*, which differs in no essential details from the earlier species *B. brachypus*; *Lartetotherium sansaniense*; *Hoploaceratherium bavaricum*; and *Alicornops simorrensis*. In Western Europe the short-limbed species *Alicornops alfabrensis* Cerdeño 1989 occurs, apparently derived from *A. simorrensis*. There are

only two immigrants: *Aceratherium incisivum* and "Dicerorhinus" *schleiermacheri*, which continue together with the latest survivor, *Brachypotherium*, into MN 10 and later. The last appearance of these forms is masked by their sparse fossil record. Only "Dicerorhinus" *schleiermacheri*

transgresses the late Miocene/early Pliocene boundary, continuing in the early Pliocene as "D." *megarhinus*.

The Elasmotherini and other middle Miocene lineages became extinct in the Eastern Mediterranean at this time and were replaced by an Asian-African rhinoceros fauna.

The Central Asian lineage *Chilotherium* s.l. and the African lineage *Ceratotherium neumayri* invade Southeastern Europe and the eastern margin of Central Europe at this time.

There are several occurrences of *Chilotherium* reported from Italy, France, Greece, and Spain, but currently the evidence can only sufficiently support its occurrence in Greece. The French and Spanish remains have been assigned by Cerdeño (1989) to *Alicornops alfambrensis*. The chronologically long-ranging genus *Stephanorhinus pikeriensis* first occurs in terminal late Miocene horizons of Southeastern Europe and portions of the Eastern Mediterranean. The single record of a true *Diceros* from Kayadibi suggests some ecological differences within the Eastern Mediterranean. *Ceratotherium neumayri* shows some size increase, together with a slight tendency of progressive hypsodonty during the late Miocene interval.

Three subgenera of *Chilotherium* arise from the second Asian Aceratheriinae radiation. Two subgenera there can be traced back to the middle Miocene. Their arrival in the Eastern Mediterranean region begins with *Chilotherium (Subchilotherium) intermedium*, recorded from only one Anatolian locality. The few undetermined remains from France and Spain may probably belong to this species. *Chilotherium (Acerorhinus)*, also known from Eastern Asian middle Miocene age horizons, lacks the specializations typical of *Chilotherium* s.s. It occurs at several Anatolian localities with the species *zernowi*, known also from Eastern Europe. The Anatolian record seems to be confined to MN 9 and MN 10, possibly extending into MN 11. Its Eastern Asian relatives are more advanced.

The evolutionary relationships of species included within *Chilotherium* s.s. are not yet well understood. The most primitive form dentally, *Chilotherium samium*, first occurs in Anatolia possibly as early as late MN 10, but certainly by MN 11. The holotype *Ch. samium* comes from an unknown horizon at Samos. *Chilotherium kiliasi* (Geraads and Koufos 1989) occurs at Pentalophos (MN 10). This species was originally described as being referable to *Aceratherium*, but indeed it is typical of a primitive *Chilotherium* and may be closely related to *Chilotherium samium*, the only species with female mandibles not broadened anteriorly. It has to be added that the larger form of this species, reported in Heissig (1975) from Çorak Yerler, is possibly another species belonging to the same lineage.

Chilotherium kowalevskii is the only species of this time period exhibiting characters diverging from other members of this group. *Chilotherium habereri*, also known from China, first occurs a little earlier in time (MN 10) and is possibly closely related to the Maragheh species *Ch. persiae* (for its stratigraphic and chronologic record at Maragheh, see Bernor et al., this volume). It is replaced in MN 12 by the latest and largest *Chilotherium* species, *Ch. schlosseri*, which may very well be derived from *Ch. habe-*

ri; however, intermediate forms are known only from Eastern Asia. All of these species have near relatives in Eastern and Central Asia, but the lineages are difficult to disentangle. *Chilotherium habereri* seems to be representative of the central stock, from which at least the larger and more hypsodont middle and late Turolian species *Ch. anderssoni* (the Chinese genotype species) and *Ch. schlosseri* are derived. The Maragheh species *Ch. persiae* is also a close relative.

Despite our poor understanding of European rhinoceros ecology, rhino faunal development is consistent with the evolution of a continuous woodland environment. The extinction of most rhino species during the late Miocene corresponds to progressive cooling and development of more temperate woodlands.

To the south and southeast we find a gradual change in landscape to increasingly open habitats and, at the same time, the extension of this more Mediterranean type of climate to the north. Nevertheless, we may conclude fundamental differences between the late and middle Miocene rhino faunas by the distinct faunal break found in the Eastern Mediterranean region. The dominant form, *Ceratotherium neumayri*, was at least partly a grass eater, whereas the genus *Chilotherium* most likely occupied diverse ecological niches, indicated by the number of species. Certainly there were a number of non-graminean herbs that formed their diet. The most brachydont *Chilotherium (Acerorhinus)* may have been the only widespread browser in this region. Only one locality has yielded the African browsing rhinoceros genus *Diceros*, indicative of more densely vegetated areas.

The Pliocene

The basal Pliocene marks yet another turnover in rhinoceros faunas. Very few late Miocene rhinoceros species persist during the Pliocene in the Eastern Mediterranean. Also, Central and Southeastern Europe have very few rhinoceros-bearing localities. Quite to the contrary, Western and Southern Europe have numerous Pliocene rhinoceros localities.

The Mio–Pliocene boundary includes the principal extinction event for European rhinoceroses. All Aceratherini and Teleoceratini disappear from Europe and the Eastern Mediterranean. From MN 14 onward, *Brachypotherium*, *Diceros*, and *Ceratotherium* are restricted to Africa. In Europe only one major lineage has survived the Mio–Pliocene boundary: “*Dicerorhinus*” *schleiermacheri*. This lineage evolves through the successive Pliocene species: “*D.*” *schleiermacheri*—“*D.*” *megarhinus*—*D. jeannvireti*.

“*Dicerorhinus*” *megarhinus* is the only known basal Pliocene rhinoceros. “*Dicerorhinus*” *miguelcrusafonti*, a species of unknown origin, first appears during MN 15 and has a geographic distribution restricted to the Iberian Peninsula

and southern France. “*Diceros*” *megarhinus* is replaced at the beginning of the late Pliocene by its descendant, “*D.*” *jeanvireti*. “*D.*” *jeanvireti* coexists for a short time with the smaller form *Stephanorhinus etruscus*, which itself is probably derived from the Turolian form *St. pikermiensis*. *Stephanorhinus etruscus* is the only rhinoceros species that survives into the Pleistocene.

We have very little knowledge of the Eastern Mediterranean rhino fauna during this temporal interval. Most specimens are insufficient for determination. Some bones from the Turkish MN 17 locality Gülyazi (Gauss/Matuyama boundary, ca. 2.6 Ma; Bernor and Lipscomb 1991; Steininger et al. this volume) conform in their size to *St. etruscus*, but the morphological characters of this form are atypical for the species. Two lower molars of undetermined age from Kobasi, provisionally referred by Heissig (1973) to *Stephanorhinus ringstroemi*, may actually be referable to either “*D.*” *scheleermacheri* or “*D.*” *megarhinus*.

Nearly all of the European and Western Asian Pliocene rhinos had brachydont cheek teeth and were browsers. The only rhino with somewhat higher crowns was the Western European species “*Dicerorhinus*” *miguelcrusafonti*, suggesting an adaptation to a drier Mediterranean climate in Spain and southern France during MN 15. Knowledge of Eastern Mediterranean Pliocene rhino faunas is insufficient to make meaningful comparisons with the rest of Europe.
